## Practical 12

### Investigating Electrochemical Cells

## Method

- For each half cell, clean the 2 strips of metal (if you have an ion/ion half cell) with sandpaper so there is surface area exposed for the reactions to occur.
- Put each piece of metal into 100 cm<sup>3</sup> beaker containing 50 cm<sup>3</sup> of a solution which contains the metal's ions.
- To create a salt bridge soak a strip of filter paper in KNO<sub>3</sub>. Place the salt bridge so its ends are dipped into the 2 beakers with the different metals (see diagram below).
  - Used to complete the circuit by allowing movement of ions and balancing charges. Use of K<sup>+</sup> and NO<sub>3</sub><sup>-</sup> minimises the chance of precipitates forming (soluble salts).
- Use wires and crocodile clips to connect each piece of metal to a voltmeter and read and record the electrode potential.
  - Use a high resistance voltmeter to find the value of the E<sub>cell</sub>.
- Repeat steps 1-5 with other pairs of metals.

## Diagram

## Key Points

- Standard conditions: **1 mol dm<sup>-3</sup>** solutions, gases at **100 kPa**, **298 K**.
- If the value is negative, the electrodes are the wrong way round.
- Remember, for a thermodynamically feasible process, EMF has to be **positive**.
- EMF = E<sub>R</sub> - E<sub>L</sub>**, where R - right hand cell, where the reduction occurs, and E<sub>L</sub> - left hand cell, where oxidation occurs.

## Safety

- Some solutions are **too dangerous** to use at 1 mol dm<sup>-3</sup> (e.g. silver nitrate which is highly oxidising).
- Zinc sulphate and iron (II) sulphate are **harmful to the environment** therefore have to be disposed of safely.

- Electrodes must be made from an **inert** substance and cannot be made from a metal that reacts with water (e.g. Mg).
- Differences between experimental values and theoretical values usually stem from the **conditions** not being standard.
