Energy transfer during exothermic and endothermic reactions

When chemical reactions occur, **energy** is **transferred** to or from its **surroundings** – it is **conserved**.

- The amount of energy at the beginning is the same as at the end.

Exothermic reactions

- An **exothermic reaction** is one that **transfers energy to the surroundings** so the **temperature** of the surroundings **increases**.
- Examples of exothermic reactions include **combustion**, many **oxidation reactions** and **neutralisation**.
- Everyday examples of exothermic reactions include **self-heating cans (e.g for coffee)** and **hand warmers**.

Endothermic reactions

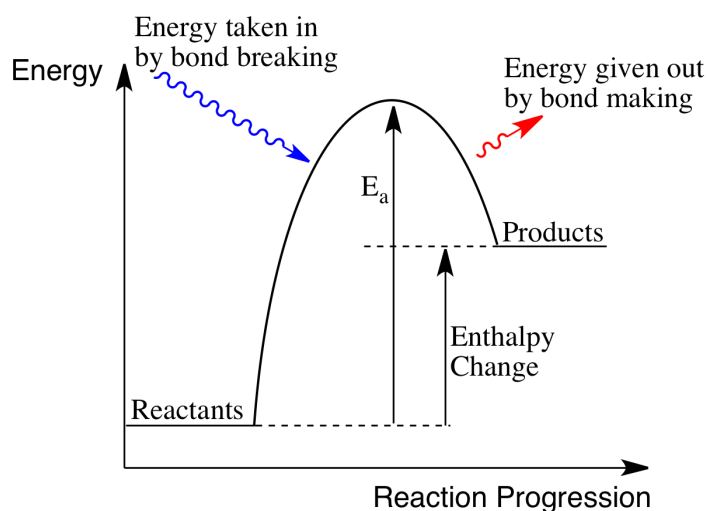

- An **endothermic reaction** is one that **takes in energy from the surroundings** so the **temperature** of the surroundings **decreases**.
- Examples of endothermic reactions are **thermal decomposition** and the **reaction of citric acid and sodium hydrogencarbonate**.
- Some **sports injury packs** are based on endothermic reactions.

Reaction profiles

Basics

- Chemical reactions can occur only when reacting particles **collide with each other** and with **sufficient energy**.
 - **Activation energy** is the minimum amount of energy that particles must have to react
- **Reaction profiles** can be used to show the **relative energies** of **reactants** and **products**, the **activation energy** and the **overall energy change** of a reaction.

Endothermic reaction energy profile

Exothermic reaction energy profile

Bond energies

The energy change of reactions

- During a chemical reaction:
 - Energy must be **supplied** to **break bonds in the reactants**
 - Energy is **released** when **bonds in the products are formed**
 - Energy needed to break bonds and energy released when bonds are formed can both be calculated from **bond energies**
 - **Sum of energy to break bonds – sum of energy released when bonds form = overall energy change**
 - If the overall energy change is **negative** the reaction is **exothermic**
 - If the overall energy change is **positive** the reaction is **endothermic**
- Energy needed to break > energy released **ENDOTHERMIC**
- Energy needed to break < energy released **EXOTHERMIC**

Using bond energy data - example

Bond energies

Bond	Energy (kJ/mol)
N≡N	946
H-H	436
N-H	389

Overall equation: $\text{N}_2 + 3\text{H}_2 \rightarrow 2\text{NH}_3$

- Energy in the reactants/bonds broken
 - $1 \times \text{N}\equiv\text{N} (1 \times 946) = 946$

- $3 \times \text{H-H} (3 \times 436) = 1,308$
- Energy in the products/bonds formed
 - $6 \times \text{N-H} (6 \times 389) = 2,334$

Overall energy change = $\Sigma(\text{bonds broken}) - \Sigma(\text{bonds formed})$

$$(946 + 1,308) - (2,334) = -80 \text{ kJ/mol}$$

- This is a **negative** overall energy change, therefore the reaction is **exothermic**.
